

# A connective differentiation of textual production in interaction networks

Renato Fabbri<sup>1, a)</sup>

*Instituto de Física de São Carlos, Universidade de São Paulo (IFSC/USP)*

(Dated: 17 October 2015)

This paper explores textual production in interaction networks and its relation to topological measures. Measures were taken from open email lists interaction networks. Texts from the email messages were grouped by source: peripheral, intermediary and hub sectors. Correlation of textual and topological measures were observed for the entire network and for each connective sector. The formation of principal components is used for further insights of how measures are related. Network sectors presented discrepant linguistic elaborations and each principal component exhibit predominance of textual or topological measures. Textual discrepancies, correlation and principal components corroborate the stability of such interaction networks reported in previous works. Noteworthy is that the difference in textual production is more prominent between sectors of the same network than between different networks or even same sectors of different networks.

Keywords: statistical physics, complex networks, natural language processing, text mining, pattern recognition, social network analysis, anthropological physics

## I. INTRODUCTION

Textual production has received considerable attention from the social network analysis community. Sentiment analysis and vocabulary compilation are among a number of examples<sup>6</sup>. The relation of topological and textual measures is the subject of this article, for the following reasons:

- This relation has been set aside in literature, with scattered and vague suggestions of mutual implications of the text produced and topological characteristics of the agents in the network<sup>6</sup>.
- The results ease understanding of human interaction, which is useful for the observation of personality and cultural “types”<sup>3</sup>.
- There are hypothesis about verbal differentiation of network sections, derived from a previous article by the same authors<sup>7</sup>, some of which are herein confirmed.

Next section exposes materials used for this research, its textual and network facets. Section III explains the analysis roadmap, with the measures chosen and methods for understanding data. Section IV is dedicated to detailing results and discussion. Section V has concluding remarks and further works envisioned. The Appendix give directions on data and scripts while Supporting Information hold further tables, figures and results still to interpret.

## II. MATERIALS

Email list messages were obtained from the GMANE email archive<sup>?</sup>, which consists of more than 20,000 email lists and more than 130,000,000 messages<sup>?</sup>. These lists cover a variety of topics, mostly technology-related. The archive can be described as a corpus with metadata of its messages, including sent time, place, sender name, and sender email address. The GMANE usage in scientific research is reported in studies of isolated lists and of lexical innovations<sup>?</sup>?

We analyzed many email lists (and data from Twitter, Facebook, IRC and Participa.br) but selected only four in order to make a thorough analysis, from which general properties can be inferred. These lists, selected as representative of both a diverse set and ordinary lists, are:

- Linux Audio Users list<sup>11</sup>, with participants holding hybrid artistic and technological interests, from different countries. Abbreviated as LAU from now on.
- Linux Audio Developers list<sup>12</sup>, with participants from different countries. A more technical and less active version of LAU. Abbreviated LAD from now on.
- Development list for the standard C++ library<sup>13</sup>, with computer programmers from different countries. Abbreviated as CPP from now on.
- List for the discussion of the election reform<sup>14</sup>. Abbreviated ELE from now on.

The first 20,000 messages of each list were considered, with total timespan, authors, threads and missing messages indicated in Table I. Furthermore, additional networks from Twitter, IRC and Participa.br are scrutinized to grasp the generality of the results derived mainly from email lists.

---

<sup>a)</sup>Electronic mail: [fabbri@usp.br](mailto:fabbri@usp.br)

Typos, *leetspeak*, slang and invented words pose some challenges to current analysis which influenced the methodology to employ numerous metrics for the texts. Future work might bring these entries to forefront as neologisms and other linguistic innovations.

### III. METHODOLOGY

#### A. Network formation, topological measures and Erdős sectioning

Figure 1 is illustrative of the formation of interaction networks. Avoiding identical repetition of content, Please refer to<sup>7</sup> for:

- further details on network formation.
- A concise consideration of the basic topological measures of vertex  $i$ : degree  $k_i$ , in-degree  $k_i^{in}$ , out-degree  $k_i^{out}$  strength  $s_i$ , in-strength  $s_i^{in}$ , out-strength  $s_i^{out}$ , betweenness centrality  $bt_i$ , clustering coefficient  $cc_i$ .
- A specification of the symmetry measures for a vertex  $i$ : asymmetry  $asy_i$ , mean of asymmetry of edges  $\mu_i^{asy}$ , standard deviation of asymmetry of edges  $\sigma_i^{asy}$ , disequilibrium  $dis_i$ , mean of disequilibrium of edges  $\mu_i^{dis}$ , standard deviation of disequilibrium of edges  $\sigma_i^{dis}$ .
- The partitioning of the real network in periphery, intermediary and hub sectors through a comparison of the real network with an Erdős-Rényi network with the same number of vertices and edges.

Such partition of the network is called “Erdős sectioning” and is herein performed with degree  $k_i$  unless stated otherwise.

#### B. Textual measures

This work focuses on the most simple measures from texts, as they proved sufficient for current step. Considered measures are:

- Frequency of characters: letters, vowels, punctuations and uppercase.
- Number of tokens, frequency of punctuations, of known words, of words that has wordnet synsets, of tokens that are stopwords, of words that return synsets and are stop words, etc.
- Mean and standard deviation for word and token sizes.
- Mean and standard deviation of sentence sizes.
- Mean and standard deviation of message sizes.

FIG. 1. The formation of interaction networks from email messages. Each vertex represents a participant. A reply message from B to a message from A is regarded as evidence that B has received information from A and yields a directed edge. Multiple messages add “weight” to a directed edge. Further details are given in<sup>7</sup>.

- Fraction of morphosyntactic classes, such as adverbs, adjectives and nouns, represented by POS (Part-Of-Speech) tags.

To such measures are dedicated Tables II, III, IV, V, VI, VII.

This choice is based on: 1) the lack of such information in literature, as far as authors know; 2) potential relations of these incidences with topological aspects, such as connectivity; 3) the interdependence of textual artifacts suggests that simple measures should reflect complex behaviors and more subtle aspects. A preliminary study, with the complete works from Machado de Assis, made clear that these measures vary with respect to style<sup>8</sup>.

#### C. Relating text and topology

The topological and textual measures were related by:

1. incidences of linguistic traces in hub, intermediary and peripheral network sectors, which are delimited by topological criteria.
2. Correlation of measures of each vertex, easing pattern detection involving topology of interaction and language used.
3. Principal components formation derived from usual PCA.

An adaptation of the Kolmogorov-Smirnov test was used to observe differences in textual content, as follows. Be  $F_{1,n}$  and  $F_{2,n'}$  two empirical distribution functions, where  $n$  and  $n'$  are the number of observations on each sample. The two-sample Kolmogorov-Smirnov test rejects the null hypothesis if:

$$D_{n,n'} > c(\alpha) \sqrt{\frac{n+n'}{nn'}} \quad (1)$$

where  $D_{n,n'} = \sup_x [F_{1,n} - F_{2,n'}]$  and  $c(\alpha)$  is related to the critical region  $\alpha$  by:

$\alpha$	0.1	0.05	0.025	0.01	0.005	0.001
$c(\alpha)$	1.22	1.36	1.48	1.63	1.73	1.95

We need to compare empirical distribution functions, therefore  $D_{n,n'}$  is given, as are  $n$  and  $n'$ . All terms in equation 1 are positive and  $c(\alpha)$  can be isolated:

$$c(\alpha) < \frac{D_{n,n'}}{\sqrt{\frac{n+n'}{nn'}}} = c'(\alpha) \quad (2)$$

When  $c'(\alpha)$  is high, low values of  $\alpha$  favor rejecting the null hypothesis. For example, when  $c'(\alpha)$  is greater than  $\approx 1.7$ , one might assume that  $F_{1,n}$  and  $F_{2,n'}$  differ. More importantly for us is that  $c'(\alpha)$  is a measure of distance between both distributions<sup>19</sup>. We use collections of these values for deriving hypotheses about how different are the underlying mechanisms of the collections.

## IV. RESULTS AND DISCUSSION

The most important result in this article is the extreme differentiation of each Erdős sectors with respect to the texts produced. For example: hubs use more contractions, more adjectives, more common words, and less punctuation if compared to the rest of the network, specially the peripheral sector. In general, the rise or fall of a metric is monotonic along connectivity, but some of them reached extreme values in the intermediary sector.

Next sections summarize results of immediate interest and further insights can be obtained by skipping through the tables and figures in the Supporting Information document.

### A. General characteristics of activity distribution among participants

Hubs and periphery swap fractions of participants and activity: while peripheral sector has  $\approx 75\%$  of participants, it produces  $\approx 10\%$  of all messages. Conversely, hubs sector present  $\approx 10\%$  of participants and produces  $\approx 75\%$  of all messages. Fewer threads are created in proportion to total messages sent by the hubs, while threads created by the periphery are twice as frequent as general peripheral messages. This suggests a complementarity between peripheral diversity and hub specialization which, on its turn, deepens the understanding of the interaction network as a meaningful system, notably if yielded by online activity. These assertions are condensed in Table I.

### B. Characters

Peripheral vertices use more punctuation characters, digits and uppercase letters. Hubs use more letters and vowels among letters. The use of white spaces does not seem to have any relation to connectivity, with the exception that the intermediary presented a slightly lower incidence of spaces than both peripheral and hub sectors. The total number of characters in ELE list, in the 20 thousand messages, is more than three times what other lists exhibited. This suggests peculiarities related to communication conventions and style (see Appendix A 1) and were found not related to topological features. Further information is given in Table II.

### C. Tokens and words

The largest average size of tokens is from the most wordy list (ELE). This implies that it has more characters, tokens, and characters per token in comparison to the other lists. The longer words used by hubs might be related to the use of a specialized vocabulary. Although the token diversity ( $\frac{|tokens \neq|}{|tokens|}$ ) found in peripheral sector is far greater, this result has the masking artifact that the peripheral sector corpus is smaller, yielding a larger token diversity. This can be noticed by the token diversity of the whole network, which is lower than in any of the sections. This same results apply to the lexical diversity ( $\frac{|kw \neq|}{|kw|}$ ).

Punctuations among tokens are less abundant in hubs, and discrepancies here are larger than with characters comparisons (subsection IV B). Known words are used more frequently by hubs.

ELE and CPP both exhibit intermediaries with the more frequent production of punctuation, less frequent production of known words, and the highest incidence of words with wordnet synsets among known words. This suggests some peculiarity in network structure, such as authorities in the intermediary sector of such networks, using smaller sentences and a more intensive use of jargons, as made explicit in the following sections.

Words with synsets, among known English words, are less frequent in hubs sector, further evidencing the jargon and specialization hubs develop.

Further information is given in Table III.

### D. Sizes of tokens and words

Sizes of known words are smaller for hubs, which suggests its use of more common words, although some of the previous results suggests that hubs have a very differentiated and specialized vocabulary. Larger words seems to be related to intermediary sector, which might be related to the use of elaborated vocabulary. Further details are given in Table IV.

## E. Sizes of sentences

Hubs present the lowest average sentence size, both in characters and in tokens. We hypothesize that this smaller sentence use is related to the efficiency of hub specialization. Also, the incidence of usual known words seems to decay with connectivity, as does the number of known words with wordnet synsets. This reflects our view that connectivity is inversely proportional to diversity.

Further information is given in Table V.

## F. Messages

Connectivity was related to smaller messages in terms of characters and tokens. ELE list displayed an inverse situation: the more connected the sector, the longer the messages are. This was considered a peculiarity of the culture bonded with the political subject of ELE list, to be further verified. Regarding sentences, the size of messages seem to hold steady throughout connectivity. Further information is given in Table VI.

## G. POS tags

Lower connectivity yields more nouns and less adjectives, adverbs and verbs. This suggests that the networks collect issues important to the world by the peripheral sector. These issues are qualified, elaborated about, by the more connected participants. This is a further indicative that peripheral sectors are related to diversity while hubs relate to specialization. Further information is given in Table VII.

## H. Differentiation of the texts from Erdős sectors

Results from our adaptation of the Kolmogorov-Smirnov test suggest that the texts produced by each sector are extremely different. Intermediary sectors sometimes exhibit greater differences from periphery and hubs than these extreme sectors themselves (Tables VIII and XII). This differentiation of the three sectors is a strong indicative that the Erdős Sectioning described in<sup>7</sup> reveals meaningful sectors of the networks.

Tables VIII-XV illustrate two strong results:

- Differences of textual production of the Erdős sectors are extreme. This can be noticed from the high values on these tables, beyond reference values used for the acceptance of the null hypothesis (see Section III C).
- Differences between sectors on the same network (Tables VIII, X, XII and XIV) are greater than differences between same sector from distinct lists (Tables IX, XI, XIII and XV).

We can summarize these results stating that the extreme difference found between the texts produced the Erdős sectors are greater than that found between that of texts from different networks or from the same sector of different networks.

## I. Correlation of topological and textual metrics

Correlation of degree and strength metrics is substantially smaller for intermediary sector. Also noteworthy is the negative correlation of degree and message size (number of characters, tokens or sentences) that intermediaries presented. This and other insights can be drawn from Tables XVI, XVII and XVIII. Overall, negligible correlation is found between textual and topological metrics.

## J. Formation of principal components

Principal components formation seem to be the less stable of all results reported in this study. First component, with  $\approx 25\%$  of dispersion, relies heavily on POS tags, and slightly on sizes of tokens, sentences and messages. Second component, with almost 12% of dispersion, blends topology, POS tags and size of textual units. Third component, with about 8.5% of dispersion is mostly nouns frequency and size of textual units. Fourth and fifth components present less than 5% of total dispersion, but are included in the Supporting Information document for completeness of exposition.

Tables XIX-XXIII yield these results and further insights.

## K. Results still to be interpreted

Histogram differences of incident word sizes with and without repetition of words are constant. That is, in each email list, when a histogram of word sizes were made with all words written, and another histogram made with sizes of all *different* words, the cumulative absolute difference of the two histograms throughout the bins were found constant for all lists analysed. When all known English words were considered, the difference sums up to  $\approx 1.0$ . When stopwords are discarded, the difference found was different, but still constant, slightly above 0.5. When only stopwords were considered, the difference is  $\approx 0.6$ . When only known English words that does not have wordnet synsets are used, this difference is  $\approx 1.2$ . Appendix B and Figures 2-6 are dedicated to this histogram differences.

## V. FINAL REMARKS

This is a first systematic exploration of the relation between topological and textual metrics in human inter-

action networks, as far the author knows. Different textual features were scrutinized and were found to present evident patterns, specially in relation to topological measures and the Erdős sectors. Furthermore, results suggest that less connected participants bring external content and concepts, while hubs qualify the content. For example, periphery sectors present more nouns while hubs use more adjectives and usual words. Such findings have potential applications in the collection and diffusion of information, resources recommendation in linked data contexts, and open processes of document elaboration and refinement<sup>1,2,5,7,9</sup>.

### A. Further work

Similarity measures of texts in message-response threads has been thought about by the author, and some results are being organized. These are two hypothesis obtained from recent experiments:

- existence of information “ducts”, observable through similarity measures. These might coincide with asymmetries of edges between vertexes pairs, with homophily or with message-response threads, to point just a few possibilities.
- Valuable insights can be driven from self-similarity of messages by same authors, of messages sent at the same period of the day, etc. This includes incidences of word sizes, incidences of tags and morphosyntactic classes, incidences of particular wordnet synset characteristics and wordnet word distances.

Given current results, diversity and self-similarity should vary with respect to connectivity. Literature usually assumes that periphery holds greater diversity<sup>6</sup>, which should be further verified.

Other directions for next steps are:

- Word sets are very useful to derive and confirm hypothesis. As an example, one can observe most incident or most basic words and word types in the English language, curses or words related to food.
- Interpretation of various unveiled results, such as the one exposed in Appendix B, and Figures 2, 3, 4, 5 and 6.
- Extend word class observations to include plurals, gender, common prefixes and suffixes, etc.
- Date and time should also be addressed in textual production of interaction networks, as potentially linked to participation habits and purposes (e.g. low dispersion of sent time). This was tackled by the author for the topological characterization of interaction networks<sup>7</sup>, but left aside in this article.

- Balance token diversity with corpus size, as pointed in section IV C.
- The textual features distributions are likely to be have more than one peak or other non-trivial characteristic. Therefore, further analysis should be made for comparing measures of interest.
- Extend analysis to the windowed approach used in the article where hub, peripheral and intermediary sectors where topologically characterized<sup>7</sup>.
- For ELE list, the more connected the sector, the longer the messages are. This is the inverse of what was found in the other lists, and was considered a peculiarity of the culture bonded with the political subject of ELE list, to be further verified.
- Tackle Portuguese analysis of interaction networks, as this research have ongoing implications in Brazil<sup>9</sup>.
- Analyse other lists.
- Analyse interaction networks from other platforms such as Twitter, Facebook, LinkedIn, Diaspora, etc.
- Emotion classification has not been done and was considered out of the scope for this stage of development, but should be addressed in a near future.

Wordnet synsets incidences was studied as well, as a potentially useful way to characterize networks and sectors. Core aspects understood as useful for this research include:

- Incidence of hypernyms, hyponyms, holonyms and meronyms.
- Use and development of similarity measures of words, phrases and messages, by use of semantic criteria (Wordnet) and bag of words.

## Appendix A: Support information

### 1. Brief description of the email lists chosen

GMANE is a public email list database with some tenths of thousand of lists<sup>10</sup>. Four email lists were selected, in a similar fashion developed in<sup>7</sup>, but with MET substituted by ELE list so that all lists are in English. The lists are:

- CPP, the development list of the standard C++ library<sup>15</sup>. Dominated by specialized computer programmers.
- LAD: Linux Audio Developers list<sup>16</sup>.
- LAU: Linux Audio Users list<sup>17</sup>.
- ELE: list for discussion of the election reform<sup>18</sup>.

Table I has an overview of these lists, in terms of participants, threads and messages in each of the primitive connective sectors.

### 2. Meaning of achronims and abbreviations in the following tables

symbol	meaning
$ x $	the number of times $x$ was found
$kw$	known word
$ x \neq $	number of different $x$ found
$kwss$	known word with (wordnet) synset
$kws w$	known word that is a stopword
$ukws w$	unknown word that is a stopword
$nsssw$	word without (wordnet) synset that is a stopword

Other symbols are explained on the tables itself. Some concepts, such as *contractions*, *token* and *char* are standard in natural language processing, and the reader is invited to visit<sup>4</sup>.

$\Delta_Y$	7.44	-	-	-	6.25	-	-	-	2.08	-	-	-	9.37	-	-	-

TABLE I. Columns  $date_1$  and  $date_M$  have dates (month/day/year) of first and last messages from the 20,000 messages considered.  $N$  is the number of participants (number of different email addresses).  $M$  is number of messages.  $\Gamma$  is the number of threads (count of messages without antecedent).  $-M$  is messages missing in the 20,000 collection,  $100 \frac{54}{20000} = 0.27/100$  in the worst case. ELE notably has the fewer participants and the larger number of threads. This relation holds for pairs of lists considered: as the number of participants increase, the number of threads decrease. A similar role is observed in MET list described in<sup>7</sup>, suggesting that 1) Non-technical topics gathers fewer participants and yields shorter threads; 2) MET technological characteristic is confirmed by having intermediary  $\frac{N}{\Gamma}$  relation, between ELE (politics) and LAD (highly technical - GNU/Linux and music). These results should be further investigated in future research (see section V A). The number of threads started by hubs is significantly lower than activity for all list, this suggests creative exploitation is done by hubs, i.e. hubs acquire/absorb creativity.  $\Delta_Y$  is number of years involved in the first 20,000 messages of each list. Dates of first and last message is: Mar/13/2002 and Aug/25/2009 for CPP; Jun/30/2003 and Oct/07/2009 for LAD; Jun/29/2003 and Jul/23/2005 for LAU; finally, Abr/18/2002 and Aug/31/2011 for ELE. See section IV and subsection IV A for further directions.

TABLE II. Measures based on characters of the text produced by network participants, fairly stable. Suggested relations are: 1) punctuations of CPP, that can be expected by its programming language focus and dots and semicolon abundance in such parlance; 2) greater number of letters on ELE is expected by its political disposition; 3) not statistically clear, but higher percentage of vowels might be a sign of erudition. Most of all, number of characters incident in ELE 20,000 messages are more than the other three lists added. MET has an intermediary value of 13,137,042 characters<sup>7</sup>, above CPP, LAD, LAU and below ELE. This builds up to a dichotomic typology of networks: technical (more participants, fewer and longer threads, e.g. CPP) – political (less participants, more and shorter threads, e.g. ELE). Higher incidence of digits and lower incidence of letters seem to be associated to technical subjects. See subsection IV B for further discussion and context.

TABLE III. Basic measures on tokens, known English words, stopwords, words with and without synset. Lexical diversity is higher in LAU and LAD, probably linked to these lists hybrid technical interests (music and GNU/Linux). Larger known words and tokens are incident in ELE and LAD. ELE also exhibits larger incidence of stopwords without synsets (prolixity?). Stronger use of words with synsets that are not stopwords is held by CPP. Stopwords that have synset account for  $\approx 25\%$  of all known words, which might be an indicative of language complexity (not same as good writing though). See subsection ?? for further discussion and context.

TABLE XXIII. Composition of fifth component (threshold:  $|val| > 0.05$ ). See subsection IV J for discussion and directions.

**Appendix B: Histograms of existent and incident words**

See subsection [IV K](#), and Figures [2-6](#) for discussion and directions.

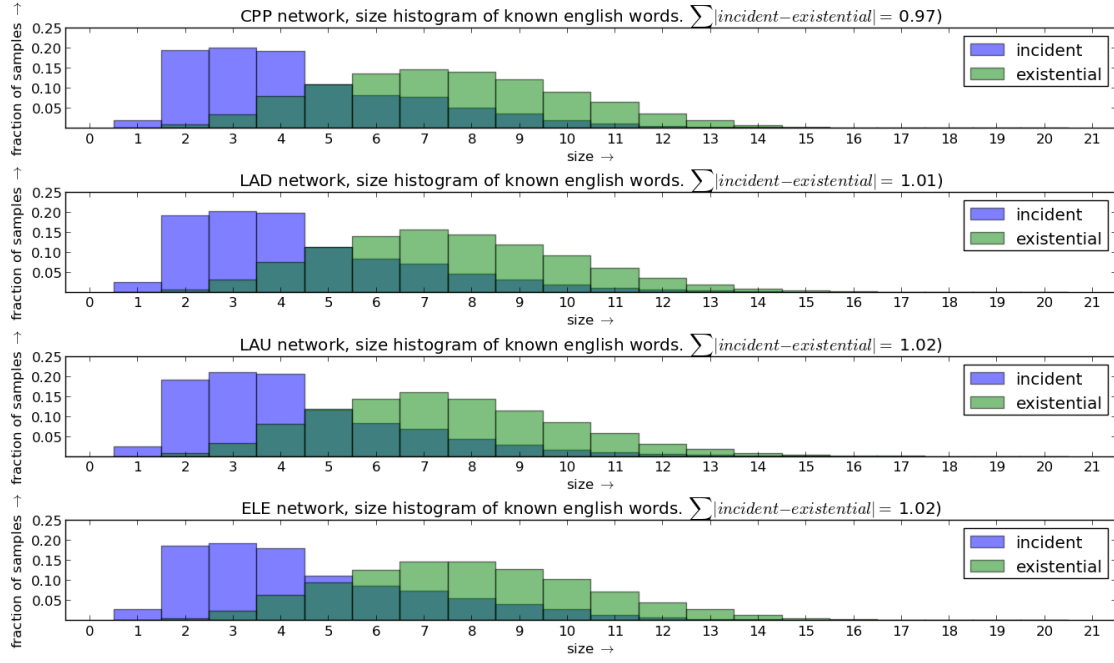

FIG. 2. Size of words that are known in English. Crossing of incident and existential sizes is around 5 (Figure 3 shows a shift to length 6-7 when consider only non stopwords). Words with three letters have maximum incidence, while most words have 7 letters. See subsection IV K for discussion and directions.

FIG. 3. Size of words that are known in English and are not stopwords. Crossing of incident and existential sizes is around 6-7 (figure 2 shows a shift to length 5 when considered stopwords). In this case, words with 4 letters have maximum incidence, while most words still have 7 letters. Exception for ELE, which exhibits maximum incidence of words with 5 letters and most words having 8 letters, which might be associated with ELE network typology discussed in tables III and . See subsection IV K for discussion and directions.

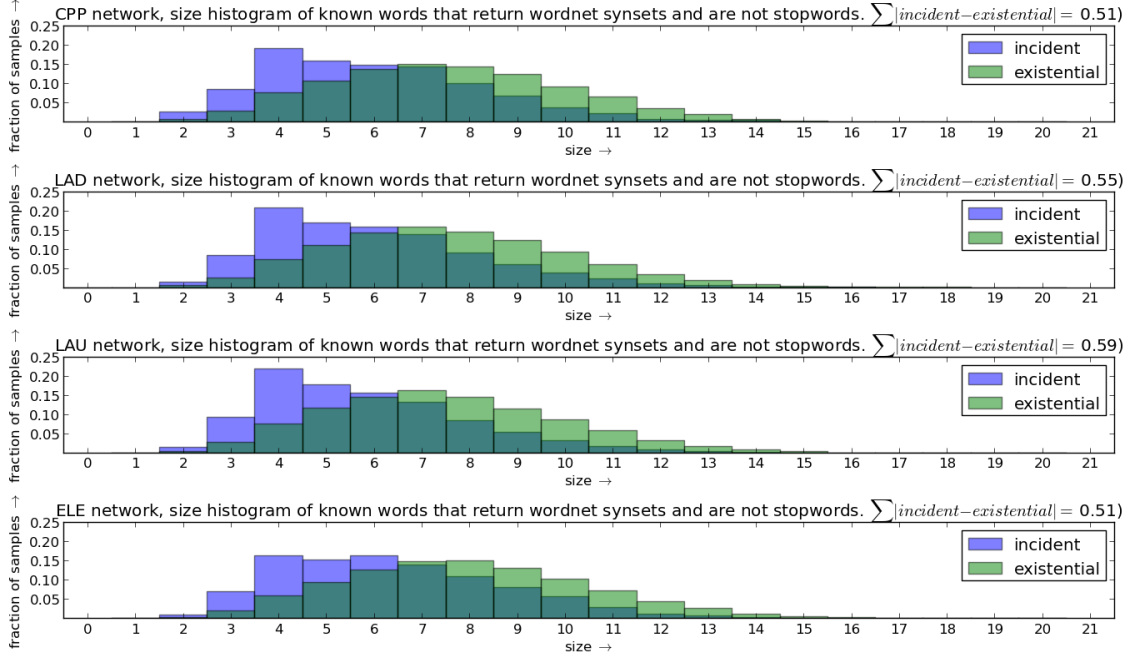

FIG. 4. Size of words that are known, are not stopwords and have synsets. Resembles figure 3. Stopword sizes histogram are in figure 5. Differences suggests  $\approx 0.5$  might be constant. LAD and LAU exquisite vocabulary (GNU/Linux, programming, sound/signal processing, music) might be responsible for higher difference of distributions. See subsection IV K for discussion and directions. See subsection IV K for discussion and directions.

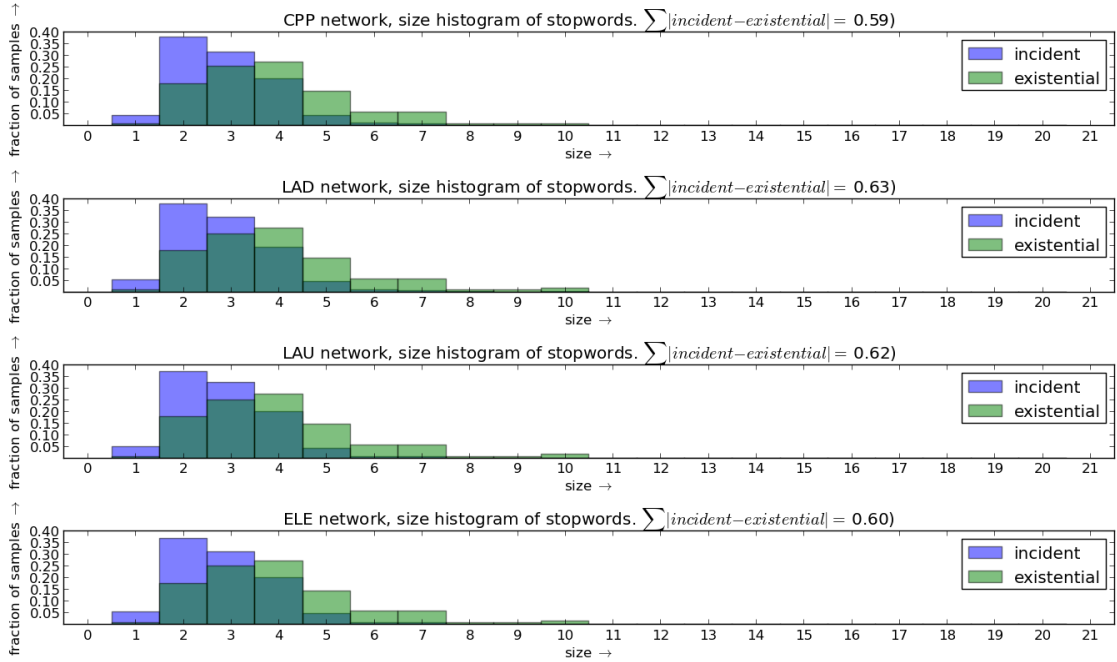

FIG. 5. Size histogram of stopwords. Stopwords with two letters are the most frequent, while most of them have four letters. Differences in distribution seem stable around  $\approx 0.6$ . See subsection IV K for discussion and directions.

FIG. 6. Size histogram of known English words that are not stopwords and do not return synsets. Differences in distribution suggests less stable behavior, with high incidence of few words high number of existing words with many letters. Observe difference  $\geq 1$ , as observed only with all known words, but even higher. See subsection IV K for discussion and directions.
